Problem 0: Gene Expression Analysis with Principal Component Analysis

This problem was inspired by a <u>Kaggle problem (https://www.kaggle.com/crawford/principle-component-analysis-gene-expression)</u>. This problem is an application of the material in Notebook 15, but based on a slightly different description and procedure.

You will carry out a PCA on gene expression data from patients with two different types of leukemia. And then you will implement kmeans clustering method on both the original gene set and the gene set reconstructed from PCA, comparing the classification accuracy bewteen two gene sets. Based on the final results, you can draw your own conclusion whether PCA is effective for this application of distinguishing leukemia patients.

Description of data set

This dataset comes from a proof-of-concept study published in 1999 by Golub, et al. It showed how new cases of cancer could be classified by gene expression monitoring (via DNA microarray) and thereby provided a general approach for identifying new cancer classes and assigning tumors to known classes. These data were used to classify patients with acute myeloid leukemia (AML) and acute lymphoblastic leukemia (ALL).

Data Cleaning

Exercise 0 (clean_data: 2.5 points).

First you need to do some data cleaning using pandas.

As you can seen from the previous cell, there are 3 data frames: X_train, X_test and y.

The X_train data frame has 7129 rows and 78 columns. Each row is a gene. The first two columns 'Gene Description' and "Gene Accession Number" encode some basic information for each gene. We will be interested primarily in so-called genes corresponding to mRNA expression values (https://www.biosyn.com/tew/The-role-of-mRNA-in-Gene-Expression.aspx), and we'll explain below how to find those. The rest of the columns hold patient information. The columns whose names consist only of an integer (such as "1", "2", "3") store patient ids. The vaules in these columns are the gene expression values. The columns with "call" in the name are the columns to measure the quality of the detection call. In this problem, you will ignore "call" columns.

X test has similar format as X train. The row labels are the same but X test has fewer patients than X train.

Lastly, the data frame y contains 2 columns. The first is 'patient', which holds patient ids intended to correspond to the patient ids in the X_train and X_test data sets. The second is 'cancer', which indicates the cancer type for each patient. There are only two types: "ALL" (acute lymphoblastic leukemia) and "AML" (acute myeloid leukemia).

Your task. To clean the training and testing data sets, create a function clean_data(X_train, X_test), which should return a new cleaned data frame X. The original data frames (X_train, X_test) shouldn't be changed. The cleaning process has 5 sequential steps:

- Step 1: Delete all the columns containing "call" in the column name.
- Step 2: Only keep the rows (or genes) whose "Gene Description" column contain the substring "mRNA".
- Step 3: Delete the "Gene Description" column, and only keep the columns with patient ids and the "Gene Accession Number" column. Then, transpose the data frame, so now each column represents a gene and each row represents a patient. Use the "Gene Accession Number" as the new column name for each gene. Use the 'patient_id' as the new row name for each patient. Note: X_test has different patient_ids with X_train.
- Step 4: Concatenate new X_train and X_test data frames into one data frame, with X_train above X_test. Then sort this combined data frame by its index in **numerical order**.
- Step 5: Convert the data type to numeric type. This last step is designed to make the later PCA and Kmeans calculations easier.

There are 2 test cells to give you some partial credits.

```
In [4]: def clean_data(X_train, X_test, y):
            # copy frames
            train = X_train.copy()
            test = X_test.copy()
            # take out call columns
            subset_train = [col for col in train.columns if 'call' not in col]
            subset_test = [col for col in test.columns if 'call' not in col]
            train = train[subset_train]
            test = test[subset_test]
            # filter rows by mRNA
            train = train[train['Gene Description'].str.contains("mRNA")]
            test = test[test['Gene Description'].str.contains("mRNA")]
            # delete gene description
            train = train.drop('Gene Description', axis=1)
            test = test.drop('Gene Description', axis=1)
            # transpose the data
            train = train.transpose().reset_index()
            train.columns = train.iloc[0]
            train = train.iloc[1:, :]
            test = test.transpose().reset index()
             ±--+ --1....--
```

Principal Components Analysis

Principal Components Analysis (PCA) is a simple yet popular and useful linear transformation technique that is used in numerous applications, such as the analysis of gene expression data. In this section, you will reimplement PCA from Notebook 15 but with a couple variations in the basic steps.

Introduction

The main goal of a PCA analysis is to identify patterns in data; PCA aims to detect the correlation between variables. If a strong correlation between variables exists, it's likely the dimensionality can be reduced. Put differently, PCA finds the directions of maximum variance in high-dimensional data and projects the data points onto a smaller dimensional subspace while attempting to preserve most of the "information" of the data, as measured by the magnitude of the projections of the original data onto the subspace.

PCA and Dimensionality Reduction

Often, the desired goal is to reduce the dimensions of a d-dimensional dataset by projecting it onto a k-dimensional subspace (where k < d). An important question is how large k should be.

We will compute the eigenvectors (the principal components) of the dataset and collect them into a projection matrix. Each of those eigenvectors is associated with an eigenvalue, which can be interpreted as the "length" or "magnitude" of the corresponding eigenvector. If some eigenvalues have a significantly larger magnitude than others, then the reduction of the dataset via PCA onto a smaller dimensional subspace by dropping the "less informative" eigenpairs is reasonable.

A Summary of the PCA Approach

In the exercises below, you will implement the following procedure.

- 1. Standardize the data.
- 2. Obtain the Eigenvectors and Eigenvalues from the covariance matrix.
- 3. Sort eigenvalues in descending order and choose the k eigenvectors that correspond to the k largest eigenvalues, where k is the number of dimensions of the new feature subspace ($k \le d$).
- 4. Construct the projection matrix W from the selected k eigenvectors.
- 5. Transform the original dataset X via W to obtain a k-dimensional feature subspace Y.

1 - Standardizing

Whether to standardize the data prior to a PCA on the covariance matrix depends on the measurement scales of the original features. Since one interpretation of PCA is that it yields a feature subspace that maximizes the variance along the subspace's axes, it makes sense to standardize the data, especially, if it was measured on different scales. Let us continue with the transformation of the data so that it has unit scale (mean=0 and variance=1), which is a requirement for the optimal performance of many machine learning algorithms.

Recall the following concepts from basic statistics:

Standardization (z-score). Let

$$\mu = \frac{1}{n} \sum_{i=0}^{n-1} (x_i)$$

be the mean of a collection of values $x_0, x_1, ..., x_{n-1}$. Let

$$\sigma = \sqrt{\frac{1}{(n-1)} \sum_{i=0}^{n-1} (x_i - \mu)^2}$$

be the (**unbiased**) standard deviation of those values. Then *standardizing the data* (or *calculating the z-scores*) means computing for each item x_i the value

$$z_i = \frac{x_i - \mu}{\sigma}$$
.

Exercise 1 (Standardize: 1 point)

Given the data matrix X, return a new matrix X_std of the same size in which each X_std[i, j] element is the standardized value (z-score) with respect to the elements in the same column, X[:, j]. Use the definition of z-score as it appears above; in particular, be sure to compute the **unbiased** standard deviation.

```
In [7]: X_std = (X - X.mean()) / X.std()
In [8]: # `Standardization`: Test cell (1 point)
                           import math
                           sum tol = 1e-4
                           print(X std)
                           print(X std.shape)
                           # Check it
                           assert X_std.shape==(72,2037), "Expected 72 rows and 2037 columns."
                           sum_X_std = sorted(X_std.sum(axis=1))
                           # Compare your solution with teacher's solution
                           print("=== First 2 elements and Last 2 elements of your solution ===")
                           print(sum_X_std[:2])
                           print(sum_X_std[70:])
                           # Check it
                           sum_tests = [(0,-867.0718922111674),(1,-776.1804067699011),
                                                                    (70,1078.304154730164),(71,1663.9557654929808)]
                           print ("=== First 2 elements and Last 2 elements of instructor's solution ===")
                           result_array = np.array([sum_tests[0][1],sum_tests[1][1],
                                                                                                        sum_tests[2][1],sum_tests[3][1]])
                           print(result_array[:2])
                           print(result_array[2:])
                           # Test elements close
                           for i,j in sum_tests:
                                       \textbf{assert} \ \ \texttt{math.isclose} \\ (\texttt{sum\_X\_std[i],j,abs\_tol=sum\_tol)}, \\ (\text{"Row "+str(i)+" should sum to "+str(j)+" both less than the sum to sum to "+str(j)+" both less than the sum to sum t

2 - Eigendecomposition - Computing Eigenvectors and Eigenvalues

The eigenvectors and eigenvalues of a covariance (or correlation) matrix represent the "core" computation of a PCA. The eigenvectors are known as the principal components, and they determine the axes of the new feature space. The eigenvalues measure the variance of the data along the new feature axes.

Covariance Matrix

One method to calculate PCA is to perform the eigendecomposition on the covariance matrix Σ , which is a $d \times d$ matrix where each element σ_{ij} is the covariance between two features i and i. The covariance between two features is calculated as follows:

$$\sigma_{jk} = \frac{1}{n-1} \sum_{i=1}^{N} (x_{ij} - \bar{x}_j) (x_{ik} - \bar{x}_k)$$

We can summarize the calculation of the covariance matrix via the following matrix equation: $\Sigma = \frac{1}{n-1} \left((\mathbf{X} - \overline{\mathbf{x}})^T \ (\mathbf{X} - \overline{\mathbf{x}}) \right)$

$$\Sigma = \frac{1}{n-1} \left((\mathbf{X} - \bar{\mathbf{x}})^T (\mathbf{X} - \bar{\mathbf{x}}) \right)$$

where \bar{x} is the mean vector $\mathrm{smathbf(\bar{x})} = \mathrm{sum(limits \{k=0\}^{n-1} x \{i\}\}$.

The mean vector is a *d*-dimensional vector where each value in this vector represents the sample mean of a feature column in the dataset.

Exercise 2 (Calculate Σ : 1 point)

Because our data has been standardized, X_std is approximately equal to $X - \bar{x}$. Calculate a covariance matrix, cov_mat, using the equation for Σ above.

```
In [9]: | shp = X_std.shape
         cov_mat = (1/(shp[0]-1)) * (X_std.T.dot(X_std))
```

```
In [10]: # `Covariance Matrix`: Test cell (1 point)
         import math
         sum tol = 1e-4
         print('Covariance matrix \n%s' %cov_mat)
         print(cov_mat.shape)
         print()
         # Check it
         assert cov_mat.shape==(2037,2037), "Expected 2037 rows and 2037 columns."
         sum_cov_mat = sorted(cov_mat.sum(axis=1))
         # Compare your solution with teacher's solution
         print("=== First 2 elements and Last 2 elements of your solution ===")
         print(sum_cov_mat[:2])
         print(sum_cov_mat[2035:])
         # Check it
         sum tests = [(0, -231.7563891769041), (1, -230.18940653827477),
                       (2035, 367.64881498520253), (2036, 382.36014302238704)]
         print ("=== First 2 elements and Last 2 elements of instructor's solution ===")
         result_array = np.array([sum_tests[0][1],sum_tests[1][1],
                                   sum_tests[2][1],sum_tests[3][1]])
         print(result_array[:2])
         print(result_array[2:])
         # Test elements close
         for i,j in sum tests:
             assert math.isclose(sum_cov_mat[i],j,abs_tol=sum_tol), ("Row "+str(i)+" should sum to "+str(j)+"
         but yours had "+str(sum_cov_mat[i]))
```

print ("\n(Passed.)")

Exercise 3 (Eigendecomposition on the covariance matrix: 1 point)

Eigenvectors and eigenvalues are numbers and vectors associated to square matrices, and together they provide the eigendecomposition of a matrix which analyzes the structure of this matrix. Even though the eigendecomposition does not exist for all square matrices, it has a particularly simple expression for a class of matrices often used in multivariate analysis such as correlation, covariance, or cross-product matrices. The eigendecomposition of this type of matrices is important in statistics because it is used to find the maximum (or minimum) of functions involving these matrices. For example, principal component analysis is obtained from the eigen-decomposition of a covariance matrix and gives the least square estimate of the original data matrix.

Calculate eig_vals (eigenvalues) and eig_vecs (eigenvectors) for cov_mat (the covariance matrix).

Hint: Because this is a symmetrical array, we need to use https://docs.scipy.org/doc/numpy- (https://docs.scipy.org/doc/numpy-1.15.0/reference/generated/numpy.linalg.eigh.html 1.15.0/reference/generated/numpy.linalg.eigh.html) for real numbers rather than np.linalg.eig (which may find solutions using complex numbers).

```
In [11]: eig vals, eig vecs = np.linalg.eigh(cov mat)
In [12]: # `Eigendecomposition`: Test cell (1 point)
         import math
         sum_tol = 1e-4
         print('Eigenvectors \n%s' %eig_vecs)
         print(eig_vecs.shape)
         print('\nEigenvalues \n%s' %eig vals)
         print(eig_vals.shape)
         print()
         # Check it
         assert eig_vecs.shape==(2037,2037), "eig_vecs: Expected 2037 rows and 2037 columns."
         assert eig_vals.shape==(2037,), "eig_vals: Expected 2037 values."
```

```
sum evec = sorted(eig vecs.sum(axis=1))
sum_eval = sorted(eig_vals)
print("=== Sum of largest 4 elements of your eig_vals solution ===")
print("Sum:",sum_eval[-4:]," = ",sum(sum_eval[-4:]))
print("=== Sum of largest 4 elements of instructor's eig_vals solution ===")
print("Sum: [79.29171678892715, 88.80223529674713, 206.78777407920407, 309.13985245025475] = 684.0
215786151332")
assert math.isclose(sum(sum_eval[-4:]),684.0215786151332,abs_tol=sum_tol), ("Your sum is "+str(sum(s
um_eval[-4:]))+" but should be ~"+str(684.0215786151332))
print ("\n(Passed.)")

3 - Selecting Principal Components

The typical goal of a PCA is to reduce the dimensionality of the original feature space by projecting it onto a smaller subspace, where the eigenvectors will form the axes. However, the eigenvectors only define the directions of the new axis, since they have all the same unit length 1, which can confirmed by the following two lines of code:

In order to decide which eigenvector(s) can be dropped without losing too much information for the construction of lower-dimensional subspace, we need to inspect the corresponding eigenvalues. The eigenvectors with the lowest eigenvalues explain the least variance about the distribution of the data; those are the ones can be dropped.

In order to do so, the common approach is to rank the eigenvalues from highest to lowest and to choose the top k eigenvectors.

```
In [14]: # Just execute this code

# Make a list of (eigenvalue, eigenvector) tuples
eig_pairs = [(np.abs(eig_vals[i]), eig_vecs[:,i]) for i in range(len(eig_vals))]

# Sort the (eigenvalue, eigenvector) tuples from high to low
from operator import itemgetter
eig_pairs.sort(key=itemgetter(0))
eig_pairs.reverse()
```

```
# Visually confirm that the list is correctly sorted by decreasing eigenvalues
print('Eigenvalues in descending order:')
for i in eig pairs:
    print(i[0],i[1][:3],"...")

Exercise 4 (Compute dimensionality reduction: 2 points)

In [17]: # `select_components`: Test cell (2 points)

After sorting the eigenpairs, the next question is "how many principal components should we choose for our new feature subspace?" A useful measure is the so-called "explained variance," which can be calculated from the eigenvalues. The explained variance tells us how much information (variance) can be attributed to each of the principal components.

You'll use a **75**% goal for the explained variance to choose the top k components. That is, select the minimum number of the k-largest eigenvalues such that

$$explained_variance = \sum_{i=0}^{k-1} \left(\frac{eigenvalue_i}{\sum_{j=0}^{N-1} \left(eigenvalue_j \right)} \right) \ge 75\%,$$

where k is the number of the top-k components to choose and the covariance matrix is $N \times N$. Store the value of k in a variable named k_use and store the explained variance from the above equation in a variable named explained_variance.

Hint: See <u>np.cumsum</u> (https://het.as.utexas.edu/HET/Software/Numpy/reference/generated/numpy.cumsum.html) function as used in Notebook 15.

```
In [16]: eig_total = sum(eig_vals)
    explained_variance = 0
    k_use = 0

for k, i in enumerate(eig_pairs):
    if explained_variance <= .75:
        ev = i[0] / eig_total
        explained_variance = explained_variance + ev
        k_use = k</pre>
```

```
import math
sum_tol = 1e-4

print("Number of Components for",str(100*explained_variance),"% of variance:",k_use)

# Check it
assert k_use==29, ("Your calculated k_use is "+str(k_use)+" but should be 29.")

# Check it
assert math.isclose(explained_variance,0.7505984465835792,abs_tol=sum_tol), ("Your explained variance is "+str(explained_variance)+" but should be ~"+str(0.7505984465835792))

print ("\n(Passed.)")

Number of Components for 75.0598446583579 % of variance: 29

(Passed.)
```

4 - Construct the projection matrix W from the selected k eigenvectors.

It's about time to get to the really interesting part: The construction of the projection matrix that will be used to transform the gene expression data onto the new feature subspace. The "projection matrix" is nothing more than a matrix whose columns are our top k eigenvectors.

The code cell below computes the $d \times k$ projection matrix W.

```
In [18]: num_features = X.shape[1]
         p = np.array(eig_pairs[0][1].reshape(num_features,1))
          for i in range(1,k_use):
              p = np.append(p, eig_pairs[i][1].reshape(num_features,1), 0)
          p=p.reshape(num_features,k_use)
          matrix_w = np.hstack(np.vsplit(p,1))
          print('Matrix W:\n', matrix_w)
          print(matrix_w.shape)
         Matrix W:
          [[-0.00940331 -0.04602751 -0.03741541 ... -0.01512247 -0.02157882
            0.02455123]
          [-0.01303358 -0.00035806 -0.00681776 ... 0.00824519 -0.03727329
            0.02460511]
          [-0.0002826 -0.00933614 -0.04544453 ... -0.02125062 -0.01634545
            0.00613641]
          [ \ 0.01198928 \ \ 0.01553509 \ \ 0.00416808 \ \dots \ -0.01282362 \ -0.04878263
            -0.0058803 ]
           [ 0.01483216 -0.00776181 -0.01263376 ... -0.03376636 -0.0237215
            -0.03499303]
           [-0.01606375 0.0044885 0.00433831 ... -0.01457857 0.00349194
            -0.00887598]]
          (2037, 29)
```

5 - Projection Onto the New Feature Space

In this last step we will use the 2037Unknown character Unknown character k-dimensional projection matrix W to transform our samples onto the new subspace via the equation

Y = XUnknown character Unknown character W, where Y is a 72Unknown character Unknown character k matrix of our transformed samples.

Shortcut - PCA in scikit-learn

For educational purposes, we went a long way to apply the PCA to the Gene Expression dataset. But luckily, there is already implementation in scikit-learn.

```
In [20]: from sklearn.decomposition import PCA as sklearnPCA
        sklearn_pca = sklearnPCA(n_components=k_use)
        Y_sklearn = sklearn_pca.fit_transform(X_std)
        print(Y_sklearn)
        print(Y_sklearn.shape)
        [[ 15.37761032
                       3.22022452 0.96875489 ... 0.27815135
                                                             7.49733916
           0.5367048

        (72, 29)
```

Note: Any differences between Y_calc & Y_sklearn may be ignored and are due to the way the data was standardized for the PCA algorithm exercises.

Kmeans Clustering

Exercise 5 (Kmeans_accuracy: 2.5 points)

Create a function kmeans_accuracy(X_std, initial_index, y_labels), which using kmeans clustering to cluster the dataset X into K clusters. K = len(initial_index). The output should be the accuarcy of clustering comparing to the y_labels. To make it easier, we will tell you to write this function in 2 steps. To give you some partial credits, we split the test into 2 cells. One is to check your accuracy on standardized original data set X_std, which has 1.5 points. The other is to check the accuracy on PCA reconstructed data set Y_calc, which has 1 point.

- **Step 1**: Performing kmeans clustering on standardized data. Given the initial_index as a list of pre-selected patient_id, generate the intial_centers from X_std, and perform kmeans clustering, return the clustering labels for all the patients.
- Step 2: Comparing the accuracy between your clustering labels and the y_labels (i.e. y['cancer']). Note: The clustering label 0 may or may not be associated with patient type "ALL", you need to figure out which cluster label is associated with which patient type.

Hint: You can use functions from Notebook 14, which are included in the cell below.

Notes:

- 1. You need to use the specified index to generate the initial centroids, instead of just using cluster number K. The inital_index is given in the test cell.
- 2. You can use any functions in notebook 14 (all needed functions are provided in the cell below) **OR** create your own functions, **OR** using the vq module from scipy.cluster package (You can use either kmeans or kmeans2 functions from scipy.cluster.vq).

```
In [23]: ## function from notebook 14
         def compute_d2(X, centers):
             """Computing the distance matrix S."""
             m = len(X)
             k = len(centers)
             S = np.empty((m, k))
             for i in range(m):
                 d_i = np.linalg.norm(X[i, :] - centers, ord=2, axis=1)
                 S[i, :] = d_i**2
             return S
         def assign_cluster_labels(S):
             return np.argmin(S, axis=1)
         def update_centers(X, y):
             \# X[:m, :d] == m points, each of dimension d
             # y[:m] == cluster labels
             m, d = X.shape
             k = max(y) + 1
             assert m == len(y)
             assert (min(y) >= 0)

        AssertionError: Your clustering accuracy on pca data set is wrong!
```

Congratulations! Now you have implemented kmeans_accuracy on both original and PCA reconstructed gene expression data set. Do you have a conclusion which method is better? It's hard to tell on this small data set. But imaging you have more genes and more patients, then performing PCA will be faster and with similar accuracy.

Visualizing the results of PCA

The remaining code cells below are optional. There is no code to write, so you can just run the cells to verify that they complete and submit the notebook. Later, when you come back to this material, you may wish to study or use the cells below as examples of different visualization techniques.

The analysis raygals that kines principle components are needed to account for 75% of the variance DC 1.2 add up to shout ~20% and
